The experimental values of \( \log_{10} T_{1/2} (\sec) \) plotted vs \( Z_d^2/\sqrt{Q_a} \) are shown to fall on a nearly universal straight line with \( \log_{10} T_{1/2} (\sec) = (9.54Z_d^2/\sqrt{Q_a}) - 51.37 \), where \( Z_d \) is the charge number of the daughter nucleus and \( Q_a \) is expressed in units of MeV. This behavior also numerically comes out of the semiclassical WKB calculation of the barrier penetration factor. The fine structure in the ratio of experiment over theory is briefly discussed.

PACS number(s): 23.60.+e

The earliest law for the systematics of \( \alpha \) decay lifetimes was formulated by Geiger and Nuttall [1]. This was the observation that \( \log_{10} T_{1/2} (\sec) \) plotted vs \( 1/\sqrt{Q_a} \), where \( Q_a \) is the \( \alpha \) decay \( Q \) value, empirically formed straight lines for a series of nuclei with the same charge number. In Fig. 1(a), I show a modern version of this plot for the \( J^P = J^P = 0^{-} \) \( \alpha \) decay data tabulated in Ref. [2]. There are 119 data points for a range of \( Z_d \) from 74 to 106, where \( Z_d \) is the charge number of the daughter nucleus. Even though the data for a given \( Z_d \) value fall on roughly a straight line, there is a large scatter between the lines for different \( Z_d \) values.

It is well known that this trend can be understood in terms of the semiclassical approximation for the decay rate

\[
W = PW_c T, \tag{1}
\]

where \( P \) is the preformation probability, \( W_c \) is the collision rate of the \( \alpha \) particle with the nuclear surface, and \( T \) is the barrier penetration factor given for \( I = 0 \) decays in the WKB approximation by

\[
T = \exp \left\{ -2 \int_{R_i}^{R_c} \sqrt{2\mu} [V(r) - Q_a] / \hbar^2 dr \right\}. \tag{2}
\]

In this expression \( R_i \) is the "touching" radius, \( R_i = R_a + R_d \), where \( R_a \) and \( R_d \) are the hard-sphere radii for the \( \alpha \) and daughter nuclei, respectively. The potential is given by \( V(r) = Z_aZ_d \epsilon^2 / r \), where \( Z_a = 2 \), and \( R_c \) is the classical turning point, \( R_c = Z_aZ_d \epsilon^2 / Q_a \). The reduced mass is \( \mu = M_aM_d / (M_a + M_d) \). Equation (2) can be integrated exactly to give

\[
T = \exp \left\{ -2Z_aZ_d \epsilon^2 \sqrt{2\mu} / Q_a R_c^2 \times \left[ \cos^{-1}(x) - x \sqrt{1-x^2} \right] \right\}, \tag{3}
\]

where \( x = \sqrt{R_i/R_c} \). The last part of Eq. (3) can be expanded in a power series in \( x \):

\[
\cos^{-1}(x) - x \sqrt{1-x^2} = (\pi/2) - 2x + x^3/3 - \cdots. \tag{4}
\]
The $x^3$ term is often dropped in the discussion of this expansion, but it is important at the level of about 1 order of magnitude in the half-life. The next-order term in $x^5$ is not important at the present level of experimental and theoretical uncertainty. The barrier penetration factor in terms of the power series expansion is

$$T = \exp \left[ -2\sqrt{\frac{2\mu}{\hbar^2}} \left( \frac{\pi Z_d e^2}{2\sqrt{Q_a}} - 2\sqrt{Z_a Z_d e^2 R_r} + \frac{Q_a R_0^{3/2}}{3\sqrt{Z_a Z_d e^2}} \right) \right].$$

(5)

The original Geiger-Nuttall rule emerges from the first term in this expansion together with the fact that the second term does not depend on $Q_a$. Further, as previously noted [3], this result suggests that $\log_{10} T_{1/2}(\sec)$ vs $Z_d / \sqrt{Q_a}$ may be a better way to plot the data. The result is shown in Fig. 1(b), where the data again form lines for a fixed $Z_d$ value, and where the scatter as a function of $Z_d$ is somewhat less than in Fig. 1(a). The scatter in Figs. 1(a) and 1(b) is due mainly to the second term on the left-hand side of Eq. (5).

Here I point out that there is an interesting interpolation between Figs. 1(a) and 1(b). Namely, if one plots $\log_{10} T_{1/2} \text{ vs } Z_d^{0.6} / \sqrt{Q_a}$, as shown in Fig. 2(a), the points fall on a nearly universal straight line. Also shown in this figure is a straight line which represents a best fit to the data. It is given by

$$\log_{10} T_{1/2}(\sec) = (9.54 Z_d^{0.6} / \sqrt{Q_a}) - 51.37,$$

where $Q_a$ is expressed in units of MeV. The rms deviation of the experimental values of $\log_{10} T_{1/2}(\sec)$ from this straight line is 0.33. The rms deviation of the straight-line fit as a function of the power of $Z_d$ is shown in Fig. 3 and is seen to have a sharp minimum at a value of about 0.6.

It is not obvious that this should follow from Eq. (1); however, numerically it does. In Fig. 2(b) I show $\log_{10} T_{1/2}(\sec) = \log_{10}(\ln 2 / W)$ vs $Z_d^{0.6} / \sqrt{Q_a}$, where $W$ is calculated from Eq. (1) and the experimental $Q_a$ are used. The theoretical results are compared to the best-fit line from Fig. 2(a). I have used $P = 1$, $R_a = 2.15$ fm, $R_d = r_0 A_d^{1/3}$, with $r_0 = 1.2$ fm, and the classical value for $W_c$ given by

$$W_c = (1/2R_c)\sqrt{2Q_a/\mu},$$

(6)

which follows from the classical motion of an $\alpha$ particle in the nucleus in a potential $V(r) = 0$ for $r < R_c$. [The results are, however, relatively insensitive to the value assumed for $V(r)$ inside the nucleus.] The radii $R_a$ and $R_d$ used above are the uniform sphere radii which are related to the rms charge radii $r_{ch}$ by $R = \sqrt{5/3} r_{ch}$ (for $r_{ch} = 1.67$ fm for the $\alpha$ particle). The theoretical points from the semi-
classical WKB approximation follow the straight-line dependence even a little better than the data \( \text{rms}=0.20 \), see Fig. 3.

The deviation between experiment and theory can be seen in more detail in the usual way [4] by plotting the preformation factor \( P \), as deduced from the ratio of the experimental and theoretical decay rates versus neutron and proton number as in Fig. 4(b). The well-known fine structure in \( P \) vs neutron number \( N \) can easily be seen with the dominant effect being a dip to \( P=0.01 \) at \( N=126 \). The top set of points in Fig. 4(b) obtained with a value of \( r_0=1.1 \text{ fm} \) illustrates the strong correlation between \( r_0 \) and \( P \). The decrease in \( P \) at \( N=126 \) is correlated with a decrease in the measured rms charge radii at \( N=126 \) [5]. However, the radius variation is only about 2%, whereas a dip of 1 order of magnitude in \( P \) would require about a 10% radius change if this were the only thing responsible. Buck, Merchant, and Perez [2] have postulated that the radius to be used for \( R_r \) should be determined not from the charge radius but by the Bohr-Sommerfeld condition for an \( \alpha \)-particle wave function inside the nucleus with a fixed well depth and a fixed number of nodes. In addition, they postulate that there is a 10% increase in the number of nodes at \( N=126 \) due to the change of valence shell structure. This increases the radius by 10% and thus accounts for the discontinuity at \( N=126 \). The \( P \) values obtained from their assumption about \( R_r \), as shown in Fig. 4(a) show about a factor of 2–3 improvement in the scatter, and the discontinuity at \( N=126 \) is mostly accounted for.

Another way to interpret the results of Buck et al. is to relate \( R_r \) for the \( \alpha \) cluster to the radius of the valence orbits. There is about a 10% increase in the rms radius of the valence neutrons when they change from the \((0h_{11/2}, 1f_{7/2}, 1f_{5/2}, 2p_{1/2}, 2p_{3/2}, 0i_{13/2}) \) major shell below \( N=126 \) to the \((0i_{11/2}, 1g_{9/2}, 1g_{7/2}, 2d_{5/2}, 2d_{3/2}, 3s_{1/2}, 0j_{15/2}) \) major shell above \( N=126 \). There should be a similar effect when the valence protons cross \( Z=82 \). The empirical \( Z \) dependence is shown on the right-hand side of Fig. 4. The lines which cross \( Z=82 \) are for neutron numbers around \(^{208}\text{Pb} \) \((N=112)\) and surprisingly do not show a discontinuity at \( Z=82 \), perhaps because \( Z=82 \) is not a good magic number for these very light \( \text{Pb} \) isotopes. Other lines on the right-hand side of Fig. 4 start at \( Z=84 \) (the \( \text{Po} \) isotopes) and show about the same trend from \( Z=84 \) to 90 as for the neutron points between \( N=128 \) and 140 on the left-hand side of Fig. 4. Thus, in summary, the comparison in Fig. 4(b) indicates a discontinuity in both \( N \) and \( Z \) centered only on the doubly magic nucleus \(^{208}\text{Pb} \). The orbit occupations of the valence protons and neutrons also influence the amount of proton-neutron correlation and hence the preformation probability. Quantitative calculations based on microscopic models have been difficult and controversial [6] and have thus far been limited mainly to the one case \(^{212}\text{Po} \) \( \alpha \) decay.

In summary, I have shown that the experimental values of \( \log_{10} T_{1/2} \text{(sec)} \) plotted vs \( Z^{0.6}/\sqrt{Q} \) fall on a nearly universal straight line. These systematics

---

**FIG. 4.** (a) On the top, the ratio of the experimental and theoretical decay rate for \( \alpha \) decay (circles) is shown with the theoretical decay rate taken from Ref. [2]. On the left-hand side the points are plotted vs neutron number \( N=N_d+2 \), and those for a given proton number \( Z=Z_d+2 \) are connected by a line. On the right-hand side the points are plotted vs \( Z \), and those for a given \( N \) value are connected by a line. (b) On the bottom, the ratio of the experimental and theoretical decay rate for \( \alpha \) decay is shown with the theoretical decay rate obtained from the present calculations with \( r_0=1.2 \text{ fm} \) (circles) and \( r_0=1.1 \text{ fm} \) (squares).
should be useful for extrapolations to more exotic nuclei and to superheavy nuclei. I also have shown that this behavior comes out numerically from the semiclassical WKB approximation. It may be useful to consider whether or not there is any simpler underlying physical interpretation of this simple functional dependence of the decay rate on $Z_a$.

Note added in proof. Other simple relations have been proposed, which are similar in spirit to mine but not the same in form. These are summarized in Ref. [7]. In particular, the form of Wapstra et al. [8] can be fitted to the data set considered here with the result, $\log_{10} T_{1/2} (\text{sec}) = \left[ (1.001 Z_a + 51.89) / \sqrt{Q_a} \right] - 51.37$, and with an rms deviation of 0.31. The form of Taagepera and Nurmia [9] and Keller and Munzel [10] can be fitted to the data set considered here with the result, $\log_{10} T_{1/2} (\text{sec}) = 1.598 \left[ (Z_a / \sqrt{Q_a} - Z_a^{2/3}) \right] - 19.94$, and with an rms deviation of 0.33.
