(Received 11 June 2011; revised manuscript received 21 November 2011; published 15 December 2011)

One- and two-neutron removal reactions from $^{19}$C and $^{20}$C have been studied using a liquid-hydrogen target at 40A MeV. A small cross section has been observed in the one-neutron removal reaction from $^{20}$C. The observed inclusive removal cross sections are compared with theoretical removal cross sections calculated using shell model spectroscopic factors and Glauber-model single-particle cross sections. The observed momentum distributions are also compared with those calculated using continuum-discretized coupled-channel methods. Good consistency between theory and experiment is shown in the one-neutron removal reaction from $^{19}$C. However, our theoretical calculation fails to reproduce the neutron removal reactions from $^{20}$C, which suggests that further improvements of the theoretical descriptions are necessary.

I. INTRODUCTION

The invention and development of radioisotope (RI) beams has opened a new era concerning many types of scientific research. Investigations on the structure of exotic nuclei far from the stability line have attracted much interest in the past two decades. Among such studies, the momentum distribution of fragments is one of the most powerful tools used to investigate the structure of exotic nuclei. Via a Fourier transformation in the polar coordinate system, the momentum distribution of the fragment reflects the spatial distribution and the angular momentum of the transferred valence nucleon(s). The halo structures of $^{11}$Li, $^{11}$Be, $^{15}$C, etc., have been established through such observations [1]. Furthermore, measurements of the momentum distribution are used to investigate the configuration of the valence nucleon(s) for unstable nuclei [2].

It is interesting to study carbon isotopes for their nuclear structure, since they have a long isotope chain ($A = 9$ to $A = 22$). Since some nuclei in C isotopes ($^{15,17,19}$C) have relatively small one-neutron separation energies ($\delta_{1n}$), the halo structure for the nuclei has been investigated. Interaction cross sections ($\sigma_I$), which are defined as the sum of reaction cross sections for the change of proton and/or neutron number in the incident nucleus, have been measured at relativistic energies (around 950A MeV) for $^{9-20}$C [3]. Data show that the nuclear radii greatly increase at $^{16}$C, but not at $^{15}$C, where a valence neutron is located in a new shell. Although the radius of $^{19}$C is much larger than those of neighbors, the radius of $^{17}$C shows no enhancement. Systematic measurements of longitudinal momentum distributions ($p_{||}$) of fragments for C isotopes, up to $A = 19$, have been made at GANIL [4] and at RIKEN [5–8]. Especially, at RIKEN, $p_{||}$ for two-neutron removal reactions have been simultaneously investigated for $^{15-19}$C isotopes. The total reaction cross sections ($\sigma_R$), which are defined by $\sigma_I$ plus inelastic scattering cross sections, have been measured for $^{15-18}$C with a C target at around 80A MeV [5,7,8] and for $^{18-22}$C with a proton target at around 40A MeV [9,10]. $\sigma_R$ of $^{18-22}$C have been successfully analyzed by the Glauber model [9,10]. $\sigma_R$ of $^{22}$C shows that a large neutron halo structure is suggested for the nuclei [9]. Theoretical calculations based on the Glauber model for $\sigma_R$ in C isotopes have been investigated in Refs. [11,12]. The $p_{||}$ distributions for one- and two-neutron removal reactions for $^{15-19}$C with a C target have been theoretically investigated using an eikonal reaction model [13].

The nuclear structure of $^{20}$C is interesting, since it may have a $N = 14$ subshell closure. Although a $N = 14$ subshell closure is suggested for oxygen isotopes [14,15], in-beam $\gamma$-ray spectroscopy performed at GANIL has shown a disappearance of the $N = 14$ subshell closure in $^{20}$C [16]. Inelastic scatterings...
on $^{208}$Pb and liquid-hydrogen targets have been investigated up to $^{20}$C [17]. The data show the need for a factor of about 0.4 decrease of the normal polarization charges from a simple shell model calculation. This suggests a large decoupling of the valence neutrons from the core. Thus, the nuclear structure of the ground state of $^{20}$C is still quite unknown. Since $p_{//}$ of fragments from $^{20}$C are sensitive to the valence neutron(s) configuration of the $^{20}$C ground state, the measurements may provide new information about the nucleus.

From an experimental point of view, a liquid and/or solid hydrogen target is attractive, since the number of atoms per unit mass is the maximum. Thus, the small intensity of RI beams can be partly compensated. It is noted that, recently, transverse momentum distributions ($p_{//}$) of fragments from $^{18,19}$C with a proton target have been measured [18]. To interpret the nuclear structure for the nuclei, the authors successfully used continuum-discretized coupled-channel (CDCC) methods [19]. CDCC analysis might be also adequate to interpret $p_{//}$. We developed our CDCC analysis code, namely HCTAK [20], and used the program to analyze the $p_{//}$ experimental data.

In the present work, we studied one- and two-neutron removal reactions from $^{19}$C and $^{20}$C using a liquid-hydrogen target at 40A MeV. In Sec. II, we describe the experimental results along with a description of the experimental setup. In Sec. III, we present our analysis methods, and give discussions. We summarize the paper in Sec. IV.

II. EXPERIMENT AND RESULTS

The experiment was performed at the Riken Projectile Fragment Separator (RIPS) [21], a part of the RI Beam Factory operated by RIKEN Nishina Center and CNS, the University of Tokyo. The experimental setup is shown in Fig. 1, which is essentially the same as that described in Refs. [9,10]. Secondary beams of $^{19}$C and $^{20}$C were produced by projectile fragmentation of the primary beam, $^{40}$Ar, at 63A MeV. The production target was Ta with a 333 mg/cm$^2$ thickness. At the first focus (F1) of RIPS, we used a wedge-shaped degrader and a parallel plate avalanche counter (PPAC) [22] to determine the beam position. At the second focus (F2), we used a plastic scintillator to give a start signal for a time-of-flight (TOF) measurement. The reaction target was made of liquid hydrogen ($t = 204$ mg/cm$^2$), a part of the cryogenic proton and alpha target system (CRYPTA) [23], and was placed at the achromatic focus (F3). Before the reaction target, three PPACs were used to track incident nuclei and to obtain the beam position and the incident angle on the target. Particles before the reaction target were identified by the energy loss ($\Delta E$) in two Si detectors, the TOF between two plastic scintillators located at F2 and at F3, and the magnetic rigidity. A stack of 160 NaI(Tl) crystals, called DALI2 [24], surrounded the target to detect any deexcitation $\gamma$ rays emitted from the fragments.

After the reaction target, particles were transported by a superconducting triplet quadrupole magnet (STQ) [25] to F4. We used the STQ to increase the transmission efficiency from the reaction target to detectors used for particle identification. The STQ also allowed us to measure TOF between F3 and F4 [26]. At F4, a plastic scintillator was used to give a stop signal of TOF. Si detectors and a NaI(Tl) detector were used to measure $\Delta E$, and the total energy ($E$), respectively. Particles after the reaction target were identified by the TOF-$\Delta E$-E method. A typical mass identification spectrum after the reaction target for the $^{20}$C projectile is shown in Fig. 2, where $Z = 6$ was selected by $\Delta E$ in the Si detectors at F4. A peak for the $^{18}$C fragment is clearly shown. On the other hand, the yield of the $^{19}$C fragment is quite small. This indicates that a two-neutron removal channel is dominant in the breakup of the $^{20}$C projectile.

The $p_{//}$ of the fragments were obtained from the TOF measured between two plastic scintillators installed at F3 and F4. The transport of fragments between these two scintillators was made only by focusing STQ, as shown in Fig. 1. The position information from PPAC at F1 was used to derive the momentum of incident fragments. The reactions of the

FIG. 1. Schematic drawing of the experimental setup in RIPS [21].

FIG. 2. Typical mass spectrum in $^{20}$C breakup. Here, $Z = 6$ was selected by $\Delta E$ in the Si detectors at F4. The energy spectrum measured in NaI(Tl) was corrected by TOF between F3 and F4. A broken line shows the $^{20}$C reaction events inside NaI(Tl).
FIG. 3. (a) Fragment longitudinal momentum distributions ($p_{//}$) for the $(^{19}$C,$^{18}$C) reaction with a hydrogen target at 40$A$ MeV. Closed circles are experimental data, while a thin solid line is a fitted result by the Lorentzian function. The thick solid line shows the summed theoretical $p_{//}$ calculated by our CDCC. (b) Theoretical $p_{//}$ for the $(^{19}$C,$^{18}$C) reaction with a proton target at 40$A$ MeV. $p_{//}$ for $E_x = 0.0$ MeV in Table I is shown by a thin solid line. $p_{//}$ for $E_x = 2.14$ MeV, 3.64 MeV, and 3.99 MeV are shown by broken, dashed, and dotted lines, respectively. A thick solid line shows the sum of the four $p_{//}$.

FIG. 4. (a) Fragment longitudinal momentum distributions ($p_{//}$) for the $(^{20}$C,$^{19}$C) reaction with a hydrogen target at 40$A$ MeV. Closed circles are experimental data, while a thin solid line is a fitted result by the Lorentzian function. Broken and dashed lines show the theoretical $p_{//}$ for $E_x = 0.0$ MeV and $E_x = 0.19$ MeV, respectively. A thick solid line shows the sum of the two $p_{//}$. (b) Fragment longitudinal momentum distributions ($p_{//}$) for the $(^{20}$C,$^{18}$C) reaction with a hydrogen target at 40$A$ MeV. Closed circles are experimental data, while a thin solid line is a fitted result by the Lorentzian function. A thick solid line shows the sum of the four $p_{//}$ ($E_x = 0.62$ MeV, 1.54 MeV, 3.28 MeV, and 3.72 MeV in Table I).
The Lorentz-transformed $p_{\parallel}$ of one-neutron removal reactions from $^{19}$C at 40A MeV is shown in Fig. 3(a). Here, $p_{\parallel} = 0$ MeV/c corresponds to the momentum of $^{18}$C with the same velocity of the incident $^{19}$C projectile. The error indicated in the figures includes a statistical error as well as an error arising from background subtraction. A Lorentzian function was used to fit the distributions. The FWHM was determined to be 83 ± 12 MeV/c after unfolding a Gaussian-shaped experimental system resolution of 18 ± 1 MeV/c in $\sigma$ for the $^{20}$C projectile. Using the estimated transmission, the one-neutron removal cross section ($\sigma_{1n}$) for the $^{19}$C projectile (the cross section of the ($^{19}$C,$^{18}$C) reaction) was obtained to be 101 ± 11 mb, which is consistent with the experimental data (106 ± 16 mb) measured at 68A MeV [18]. The errors from the transmission estimations are included besides the statistical one. It is noted that we did not observe any prominent peak of $\gamma$ rays if we selected $^{20}$B before injecting to the hydrogen target.

### III. ANALYSIS AND DISCUSSIONS

#### A. One-neutron removal reactions

The theoretical model cross sections for one-neutron removal to each final state, of spin parity $J^{\pi}$, are calculated using

$$\sigma_{1n} = \sum_{n\ell j} \left[ \frac{A}{A-1} \right]^N C^2 S(J^{\pi}, n\ell j)\sigma_{sp}(n\ell j, S_{eff}'),$$

(1)

where the $C^2S$ are the shell model spectroscopic factors and $\sigma_{sp}$ is the single-particle cross section calculated using the eikonal model assuming unit spectroscopic factor [13]. The quantum numbers of the removed neutron are denoted $n\ell j$. The $S_{eff}'$ is the effective separation energy of the neutron for $N$ the given final state. The single-particle cross sections ($\sigma_{sp}$) are assumed to be given by $\sigma_{tra} + \sigma_{diff}$, where $\sigma_{tra}$ is the contribution of proton transfer [(p,d) reaction] and $\sigma_{diff}$ is that of diffractive dissociation (elastic breakup). Shell model calculations were used for the relevant level energies and spectroscopic factors. These were performed using the code OXBASH [28]. The calculations used the WBP effective interaction [29], and a model space truncated to allow $\Omega_{1ho}$ and $\Omega_{2ho}$ excitations relative to the $p$-$sd$ ground state. The small center-of-mass correction factor $[A/(A-1)]^N$, shown in Eq. (1), with $N$ the principal oscillator model quantum number of the removed-nucleon shell, was applied to the shell model spectroscopic factors in all single-neutron removal calculations ($N = 1$ or 2 in the present calculations). The

### TABLE I. Results for one-neutron removal reactions from $^{19}$C ($^{20}$C) to bound (and unbound) final states of $^{18}$C ($^{19}$C), respectively. $E_x$ means the excited energy in the $A$-1 system, i.e., $^{18}$C ($^{19}$C) for the ($^{19}$C,$^{18}$C) reaction [the ($^{20}$C,$^{19}$C) reaction], respectively. The calculations are for a proton target at 40A MeV. $\sigma_{1n}$ include the center-of-mass correction factor $[A/(A-1)]^N$. Neutron separation energies ($S_{1n}$ and $S_{2n}$) for the $A$-1 system were calculated by the recent mass evaluation [35]. Levels with $0.58 < E_x < 4.76$ MeV in $^{19}$C contribute to the indirect two-neutron removal in $^{20}$C.

</table>
calculated results of the level energies \( E(l) \) and \( C^2S \) are shown in Table I. Total reaction cross section of the transfer reaction \( (\sigma_{\text{th}}) \) was calculated by using zero-range distorted wave Born approximation code DWUCK4 [30]. In these distorted wave calculations, the optical model parameters (OMP) for \( p^{+}A \) were taken from the global phenomenological parameters set CH89 proposed in Ref. [31]. The OMP for \( d^{+}A-1 \) were taken from the parameters set proposed in Ref. [32]. The calculated results of \( \sigma_{\text{th}} \) for the relevant levels are shown in Table I. \( \sigma_{\text{th}} \) for \( ^{10}C, ^{20}C, \) and \( ^{22}C \) with a proton target at low energy (\(~40\text{ MeV}\)) have been successfully analyzed by the Glauber-model analysis [9,10]. Thus, even for the analysis of the neutron removal cross sections, it is expected that the Glauber-model analysis works well. We calculated \( \sigma_{\text{diff}} \) by using the few-body Glauber model [33]. In this calculation, the density distributions of the core nucleus and the target nucleus, the wave functions for the valence single neutron, and the finite range parameter were necessary. The density distributions of the core nuclei were assumed to be harmonic oscillator-type distributions. Parameters of the density distributions of the core nuclei were determined to reproduce the observed \( \sigma_{\text{th}} \) with the C target at around 960\text{ MeV} (1104 \pm 15 \text{ mb} for \( ^{10}C \) and 1231 \pm 28 \text{ mb} for \( ^{19}C \) [3]). Since the target is the proton, the density distribution of the target is not necessary. To reproduce observed \( \sigma_{\text{th}} \) for \( p^{+}^{12}C \) at 40.4\text{ MeV} (371 \pm 11 \text{ mb} [34]), we determined the finite range parameter. The wave functions of the valence neutron were calculated by solving the eigenvalue problem in the Woods-Saxon potential. The effective separation energy of the valence neutron was reproduced by adjusting the potential depth. In the calculation, the diffuseness and the radius parameter for the potential were fixed to be 0.69 fm and \( 1.17A^{1/3} \) fm. For the relevant levels, \( \sigma_{\text{diff}} \) are given by the difference between the two reaction cross sections, \( \sigma_{\text{R}}(A^{C}+p)-\sigma_{\text{R}}(A^{-1}C+p) \), as summarized in Table I. The theoretical \( \sigma_{\text{th}} \) for each of the relevant levels was calculated by using Eq. (1). Since, experimentally, inclusive cross sections were measured, we simply summed the theoretical \( \sigma_{\text{th}} \) of the relevant levels below the one-neutron separation energy \( (S_{1}\text{n}) \) in the A-1 system. \( S_{1}\text{n} \) was calculated by the most recent mass evaluation [35]. For the \( (10^{C}, 18^{C}) \) reaction, the theoretical inclusive \( \sigma_{\text{th}} \) is consistent with the observed \( \sigma_{\text{th}} \). This consistency is also shown in the reaction with the Be target [13]. However, for the \( (20^{C}, 19^{C}) \) reaction, the theoretical inclusive \( \sigma_{\text{th}} \) is larger than the observed \( \sigma_{\text{th}} \) by a factor of 5.

The theoretical \( p_{f} \) was calculated by using a CDCC analysis. In the CDCC analysis, elastic breakup with nuclear and Coulomb interactions are taken into account. Here, the cross section of the breakup reaction \( a(b+x)+A\rightarrow b+x+A \) is considered. In the laboratory system, the three differential cross section (the energy spectrum of the emitted nuclei b) is expressed by [36]

\[
\frac{d^{2}\sigma}{d\Omega_{l}^{b}d\Omega_{s}^{l}dE_{b}^{l}} = \frac{2\pi}{\hbar} \frac{\mu_{R}}{P_{0}} |T_{b}|^{2} \rho \left(E_{b}^{l}\right),
\]

where \( \Omega_{l}^{b} \) and \( \Omega_{s}^{l} \) represent the direction of emission of b and x respectively, \( E_{b}^{l} \) is the energy of b in the laboratory frame, \( \mu_{R} \) being the reduced mass for a and A. \( T_{b} \) is the transition matrix element and \( \rho \)

\[
\rho(E_{b}^{l}) = h^{-6} \frac{m_{b}m_{x}m_{A}P_{b}P_{x}}{(m_{x} + m_{A}) + \frac{m_{b}(m_{b} - m_{x})}{m_{b}}P_{b}P_{x}},
\]

where \( m_{b}, m_{x}, \) and \( m_{A} \) are mass of b, x, and A, respectively, and \( P_{b}, P_{x}, P_{A} \) is the total momentum of the system in the laboratory frame. It should be noted that, in Eq. (3), independent variables are \( P_{b} = \sqrt{2m_{b}E_{b}^{l}} \) and \( P_{x} \) is a constant of motion and \( P_{A} \) is given in terms of those variables and \( P_{b}^{L} \). The T-matrix element \( T_{b} \) can be expressed in terms of the continuous S-matrix element \( S_{b}^{l}(k) \) obtained by CDCC:

\[
T_{b} = i \frac{(2\pi h)^{3}}{\mu_{b}\sqrt{2}k\sqrt{PP_{0}}} \int_{lLJM} \sqrt{2J+1} \times |Y_{l}(\hat{k}) \otimes Y_{L}(\hat{P})|_{JM} e^{i(hk_{l}+\sigma_{l}+\sigma_{J}+\sigma_{K})} S_{b}^{l}(k),
\]

where \( \delta_{lk} \) and \( \sigma_{lk} \) are the nuclear and Coulomb phase shifts of the scattering between b and x, respectively. Transforming \( (P_{b}, \hat{P}, E_{b}^{l}) \) to \( (\hat{k}, \hat{P}, k) \) in \( T_{b} \), we can calculate Eq. (2) using the laboratory-frame variables. \( p_{f} \) for b is obtained by integrating the triple-differential cross section over all solid angle of x and the finite solid angle for b. We used HCTAK [20] for the CDCC analysis. In this calculation, we needed to assume a core-plus-neutron structure for \( ^{10}C \) and \( ^{20}C \). The OMP between the valence neutron and the proton target, and the OMP between the core nucleus \( (^{10}C \text{ in } ^{19}C \text{ in } ^{20}C) \) and the proton target have been given by those proposed in Ref. [37], which can be used for the nucleon scattering of 1p-shell nuclei between 10 and 50\text{ MeV}. We used the original parameters of the OMP for the \( (10^{C}, 18^{C}) \) reaction since \( \sigma_{\text{th}} \) calculated by HCTAK is consistent with the observed one \( (754 \pm 22 \text{ mb} \text{ in } [9]) \). To reproduce the observed \( \sigma_{\text{th}} \) for \( ^{20}C \) (791 \pm 34 \text{ mb} \text{ in } [9]), we adjusted an imaginary radius of the original OMP for \( ^{20}C \). The wave function of the valence neutron was calculated by solving the eigenvalue problem in the Woods-Saxon potential. The effective separation energy of the valence neutron was reproduced by adjusting the potential depth. In the calculation, the diffuseness and the radius parameter for the potential were fixed to be 0.69 fm and \( 1.17A^{1/3} \) fm. It is noted that in this calculation any bound states were ignored, although the HCTAK calculations allow to include some bound states as well as the ground state. By the above procedure, we calculated \( p_{f} \) for the relevant levels, where we assumed each of the relevant levels as the ground state. The amplitude of the calculated \( p_{f} \) was normalized to the theoretical \( \sigma_{\text{th}} \) of each of the relevant levels. The calculated \( p_{f} \) with the proton target for the levels below the threshold were summed, as shown in Fig. 3(b) for the \( (10^{C}, 18^{C}) \) reaction and Fig. 4(a) for the \( (20^{C}, 19^{C}) \) reaction. The summed \( p_{f} \) for the \( (10^{C}, 18^{C}) \) reaction well reproduces the observed \( p_{f} \), as shown in Fig. 3(a). For the \( (20^{C}, 19^{C}) \) reaction, the shape of the observed momentum distributions can be well reproduced by the theoretical distribution, although the theoretical amplitude is much larger than the observed one, as shown in Fig. 4(a). This result, together with small \( \sigma_{\text{th}} \) for the \( (20^{C}, 19^{C}) \) reaction, may indicate that the ground state of \( ^{20}C \) has more complicated components than a simple \( ^{19}C \) core-plus-one-neutron structure.
B. Two-neutron removal reactions

For the two-neutron removal reactions, direct and indirect (one-neutron removal followed by one-neutron evaporation) two-neutron removal processes should be taken into account. We considered $p(20C,18C)t$ reaction as the direct process. Total reaction cross section of the transfer reaction ($\sigma_{\text{tr}}$) was also calculated by using DWUCK4. The OMP of $p+20C$ was taken from CH89. The OMP of $t+12C$ proposed for the $14C(p,t)12C$ reaction at $E_p=40.3$ MeV [38] was simply used as the OMP of $t+18C$. It is known that the cross sections calculated by distorted-wave Born approximation (DWBA) are always much smaller than the experimental data in the $(p,t)$ reactions. We estimated the enhancement factor as follows. We calculated angular distributions for the $14C(p,t)12C$ reaction leading to the ground state in $12C$ at $E_p=40.3$ MeV by using DWUCK4 with the OMP proposed in Ref. [38]. By comparing the calculated results with the experimental data at around 0° shown in Ref. [38], we obtained the enhancement factor ($\sim 2000$ in this case). We used this enhancement factor to evaluate the total reaction cross section for the four states ($E_x=0.19$ MeV and that with $0.62$ MeV, $0.19$ MeV, and $0.62$ MeV) are very close. If the effective interaction changes a little, the order of the levels would be changed. For example, if the order of the level with $E_x=0.19$ MeV and that with $E_x=0.62$ MeV swaps and the first $5^2+$ state becomes unbound, theoretical cross sections will approach the experimental ones. In Ref. [40], two $\gamma$ rays with $72\pm 4$ and $197\pm 6$ keV have been observed in $18C$. On the other hand, in Ref. [41], only one $\gamma$ ray with $201\pm 15$ keV has been observed in $19C$. Thus, at least two bound states exist in $19C$. Thus, if the first $5^2+$ state is unbound, the two bound states must be $1/2^+$ and $3/2^+$ and there only one $\gamma$ ray should be observed. In Ref. [42], an excited state at $1.46\pm 0.19$ MeV in $19C$ populated in the inelastic proton scattering was observed to the neutron decay. This state may correspond to the second $5^2+$ ($E_x=1.54$ MeV in Table I) in our shell model calculations. The calculated $B(E2)$ to the second $5^2+$ state is six times larger than to the first $5^2+$ state. Thus, if the first $5^2+$ state is unbound, it may be located just above the neutron decay threshold and decay by a low-energy neutron that may have been too weak to observe in Ref. [42]. For the conclusive statements for the excited states in $19C$, further experimental and theoretical investigations are needed.

In the present analysis, we assumed the peripheral reactions with the proton target. This assumption might be valid for $18C$, where the one-neutron halo structure is dominated in the ground state. However, for $20C$, central collisions may contribute to the dominant part of the neutron removal cross sections especially for the $(20C,18C)$ reaction. Theoretical descriptions including the central collisions with the proton target are anticipated.

IV. SUMMARY

One- and two-neutron removal reactions from $19C$ and $20C$ have been studied using a liquid-hydrogen target at 40A...
MeV. The longitudinal momentum distribution ($p_{/\parallel}$) of the $(^{19}\text{C},^{18}\text{C})$ reaction is broader than that previously measured with a Be target. A broad $p_{/\parallel}$ with a small cross section has been observed in the $(^{20}\text{C},^{19}\text{C})$ reaction. We calculated theoretical cross sections for one-neutron removal reactions by using the shell model spectroscopic factors and the single-particle cross sections using the Glauber model. We applied CDCC calculations to interpret $p_{/\parallel}$. For the $(^{19}\text{C},^{18}\text{C})$ reaction, the calculated results for the inclusive $\sigma_{-1n}$ and $p_{/\parallel}$ can well reproduce the observed cross sections and $p_{/\parallel}$. On the other hand, for the $(^{20}\text{C},^{19}\text{C})$ reaction, our calculations overestimated the observed $\sigma_{-1n}$ although the shape of $p_{/\parallel}$ is consistent with the observed $p_{/\parallel}$. For the $(^{20}\text{C},^{18}\text{C})$ reaction, although the shape of theoretical $p_{/\parallel}$ is consistent with the observed one, the observed $\sigma_{-2n}$ is much larger than theoretical $\sigma_{-2n}$. These discrepancies may suggest that the first 5/2$^+$ state in $^{19}\text{C}$, which is bound in our shell model calculations, may not be bound. For the conclusive statements, further experimental investigations and improvements of the theoretical descriptions are necessary. Theoretical descriptions including the central collisions with the proton target are also anticipated.

**ACKNOWLEDGMENTS**

The authors thank the members of the RIKEN accelerator staff for stable operation of the accelerators and related devices. We thank Professor J. Tostevin for providing the shell model calculations. We acknowledge support from NSF grant PHY-1068217.
